Abstract

The creation of parameter study suites has recently become a more challenging problem as the parameter studies have become multi-tiered and the computational environment has become a supercomputer grid. The parameter spaces are vast, the individual problem sizes are getting larger, and researchers are seeking to combine several successive stages of parameterization and computation. Simultaneously, grid-based computing offers immense resource opportunities but at the expense of great difficulty of use. We present ILab, an advanced graphical user interface approach to this problem. Our novel strategy stresses intuitive visual design tools for parameter study creation and complex process specification, and also offers programming-free access to grid-based supercomputer resources and process automation.

1 Motivation and Background

Only a decade ago, the solution of the partial differential equations required for the evaluation of aerospace vehicle flow-fields typically involved a single discretization zone and was performed on a single processor of a high-speed compute engine that was usually situated locally. These compute tasks were so costly in CPU cycles that the notion of performing parameter studies was usually ignored. Now, however, the flow-solvers are typically parallel codes, and the problems to be solved involve large numbers of interrelated discretization grids. The compute engines are frequently large parallel machines with multi-gigabyte memories and terabyte disk farms. Researchers have available the resources not only of their own laboratories but also those at other computer centers which are accessible via fast networks. Parameter studies are now quite feasible and are being performed on a regular basis by many researchers who require solution information throughout a given aerospace vehicle flight regime. The difficulties, however, have shifted to the manual creation of these parameter studies and to tasks associated with launching and managing the large number of jobs required by these studies. Modern aerospace flow-solvers frequently require large sets of discretization grids which describe the geometry of the aerospace vehicle. Subsequently, these solvers produce as output large collections of data files. Currently, most parameter studies are performed with two-dimensional flow solvers, but researchers are starting to use three-dimensional solvers for their parametric experiments.

Recent developments in grid-based “metacomputing” such as Globus [1] and Legion [2] have created opportunities for running parameter studies on remote networked high-performance compute servers which constitute a shared resource for participants. But these opportunities come at a price: the proliferation of job control language (JCL) to support these capabilities. This has placed an onus on users of these metacomputing grids who are typically engineering and research code users but who are not generally well prepared or enthusiastic about learning or creating the requisite control language scripts for managing distributed parameter studies. NASA is currently building a national metacomputing infrastructure, called the “Information Power Grid” (IPG) [3]. The IPG is intended to provide ubiquitous and uniform access to a wide range of computational, communication, data analysis, and storage resources, many of which are specialized and cannot be replicated at all user sites. At this time, however, the interface to the IPG is still under development.
We briefly describe the notion of a “parameter study” by giving two general examples. Simulation codes produce results which are the solution to a scientific or engineering problem defined for some set of values (“parameters”) which are the input to the code and which define the original problem. Varying these parameters typically produces different results. Varying these parameters through some specific range (the “parameter space”) will yield a set of results describing behavior in this parameter space. It is this family of related results that are sought; this is called a “parameter study” (sometimes written as “parametric study”). As a second example of a parameter study, we point to Monte Carlo simulations. Monte Carlo code runs typically must be repeated some substantial number of times in order to be able to accumulate sufficient data to be statistically meaningful, i.e., the results must be accumulated into ensemble averages. This too, then, can be considered a type of parameter study where the parameter to be varied merely is the seed for random number generation. In this case, though, the parameter varied does not actually have any significance as a physical parameter of the problem.

The end product of creating and launching parameter studies is typically a large suite of result files which must be postprocessed and/or moved to some form of long-term storage. Furthermore, parameter study users must be able to keep track of these results and log into a scientific diary such particulars as nature of the solved problem, location of the result files, history for the individual runs, and any other associated information. Being able to easily recreate and then modify the parameter study is also an important need for many users.

As a result of these concerns, we undertook to determine if there existed a parameter study capability that fulfilled the need of users at NASA Ames Research Center. The only tools that seemed applicable for these tasks were the historically related Clustor and Nimrod codes [5]. We tested and surveyed the capabilities of these tools. Both Clustor and Nimrod were able to generate and launch simple parameter studies. They also implemented an internal “meta-language” for describing parameter study creation. Additionally, they made it easy to parameterize command line arguments.

However, these tools did not fully meet the requirements of our users. Some of these requested capabilities are as follows. Users must have access to multiple job submission environments. These usage environments must include any combination of PBS [6], LSF [7], MPI, Globus, Condor [8], and Legion. Also, users require the ability to create what we call “multi-stage” parameter studies (a detailed example of this is given in section 7). Users also need a “fire-and-forget” capability, i.e., once the parameter study suite is created, it should be possible to initiate job launching and then shut down the parameter study tool entirely. We required that job submission should continue autonomously, and without the continued presence of the parameter study tool. Users also require a fairly comprehensive level of job auditing and scientific diary capability, which we see as the secretarial side of a problem solving environment (PSE). On the development side, we needed to design a parameter study tool that could be easily extended using a very high level rapid-prototyping language (such as Perl). This is because we envision using the tool as a testbed for experiments in parameter study creation models, job submission models, and complex process specification models. We also need to be able to use the tool to generate shell scripts designed for parameter study job submission and for complex process job submission (visual scripting). It is essential that the script generation process be very flexible.

2 Problem Definition

Creating and launching parameter studies without the assistance of automating tools is laborious, tedious, and error-prone. By briefly examining the stages required for this task, we will be able to discern the nature of the inherent problems. The first task in this process is to create the set of parameterized input files which incorporate the sets of values representing the parameter study. These parameter value sets are a Cartesian product of the individual sets of values over which each of the parameters of interest vary. As such, the total number of combinations (the parameter space) can quickly get to be very large, and creating these sets of input files manually is time-consuming and error-prone. Each of the resultant input files represents a user-program run. Launching these jobs involves setting up partitioned file spaces in which these jobs can be run, supplying each of the runs with all required input files, submitting the jobs, and then monitoring job progress and managing the output from these runs. We have adopted the policy that all of these functions must be automated and integrated into a single Graphical User Interface (GUI); this was our first design requirement. Our second design requirement was that of extreme simplicity of use. We believe that users are very sensitive to ease-of-use issues, and that they will ultimately avoid process automation tools that are difficult or non-intuitive in use. The third design requirement is that a parameter study tool must be able to automatically self-document the actions it performs. If it cannot do this, users will very quickly be mired in a morass of hundreds, even thousands, of old runs whose origin and purpose are no longer obvious. This therefore forces a
complete parameter study tool to be part PSE and part scientific diary. The fourth design requirement is that of job submission flexibility in a scientific computation environment that is currently in flux. This is because “Grid-based” computing has added new complexities and new layers of JCL to the task of submitting jobs. ILab meets all of these four user requirements.

3 Basic Assumptions and Requirements for Distributed Processing

We have started with two basic assumptions about NASA’s distributed computing environment into which jobs will be launched. The first is the need to maintain production level capability. This has significant implications, because all compute-intensive application processing must occur under the aegis of a job scheduler and queuing system. Modern computer centers require jobs to start through a scheduler because any other manner of submitting to shared computational resources would violate “good neighbor” policy. The second assumption about our distributed computing environment is that it should be able to leverage the Globus metacomputing middleware currently being developed at Argonne National Laboratory. It must also be possible for parameter study users to be able to bypass the Globus layer and still submit jobs into a distributed environment. This has resulted in a GUI design which incorporates several job models for spawning parameter studies in a distributed fashion.

4 ILab: The IPG Virtual Lab

We describe the more important features of the ILab parameter study tool. In particular, we will discuss the parameterization operations and also some aspects of the internal coding design.

4.1 Parameterization of Program Input Files

In order to minimize the difficulty of building a set of parameterized input files, we have created within ILab an integrated, special-purpose text editor. This editor, in fact, has unusual editing capabilities: it functions exclusively to allow the graphical selection of the appropriate parameter data fields and allows the user to designate the set of values for each of the candidate parameterized fields. This parameterizer is depicted in Figure 1. The value sets can be specified either as a list or by min/max/increment. During this process, the user first selects (highlights) with the mouse those ASCII text fields within the input file which will be parameterized. In Figure 1, “beta” and “reynum” (known to ILab as Parameter1 and Parameter2) have already been parameterized; their value sets are displayed in the left window. Currently the user is specifying the third parameter in the “Set Param Values” dialog. If several fields must be parameterized in tandem (example: multiple occurrences of, say, “timestep” for each of several related discretization zone input files), the user can be selected at this stage and parameterized in unison. After text selection of the appropriate fields, the user enters a list or range of values for the selected fields. Lastly, the set of parameterized input files is generated. These files constitute an n-dimensional Cartesian product of the individual parameter sets. As a simple example, if three input values are to be parameterized (a 3-dimensional parameter space), the first with the set of values \{1, 2, 3, 4\}, the second with \{hello, goodbye\}, and the third with \{3.14, 2.718, 1.618\}, then a total of 4 x 2 x 3 = 24 parameterized files will be produced.

Because the file parameterizer is integrated within the ILab GUI and because its use is intuitive, the process of parameterization of the input files has been made quite trivial. Additionally, a “most-recently-used” (MRU) capability saves the current parameterization state for future reference and for re-use or modification.

4.2 Job Masking Capability

One of the necessities of a parameter study program is to provide “masking” capability for a set of parameterized input files. Users require this ability since they know that certain parameter combinations will produce an unsuccessful run of the scientific program under consideration. Typically, they want to specify combinations of parameter values that will be excluded from the set of input files and their associated script files. ILab’s “Edit Parameters” screen - the special purpose editor described in section 4.1 - has a pop-up dialog dedicated to this purpose. Users can enter any number of masking rules, and each rule must specify two or more parameter comparisons. For example, if the user is varying Parameter1 from 1 to 10, and Parameter2 from 55 to 75, and wants to exclude those combinations where Parameter1 is greater than 9 and Parameter2 equals 60, the masking rule would be entered as:
This syntax, which is the same in Perl, C, C++, and Java, was chosen since users are likely to be familiar with it. The names Parameter1 and Parameter2 are assigned in order by ILab to the values being parameterized. (ILab, of course, has no way of knowing the actual names of parameters in the user’s input files since there is no requirement that the input have labeled data. In the example in Figure 1, it just so happens that the user is parameterizing a Fortran “namelist” file with labeled fields, but ILab itself only requires that the input be ASCII.) By using Perl’s “eval” function, we can easily interpret the above rule with minimal parsing, and use it to delete job objects from the user’s list of experiments.

4.3 Coding Model and Language Choice

We have chosen to construct our ILab GUI using Perl5 and the Tk user interface construction tool kit. In addition, we have used the Perl generation capabilities of the “SpecTcl” Tk GUI generation IDE [9], a free software tool available from Sun Microsystems. Our choice of Perl5 was based on its strong character string manipulation and built-in regular expression capabilities, strong list and sortable associative-hashtable datatypes, and its simple-to-use object-oriented features. Also, Perl is relatively ubiquitous and is amongst the fastest interpreters commonly available today. Altogether, these features make Perl an excellent choice for true rapid-prototyping. Though we cannot exactly quantify the savings in the coding effort, we believe, based on prior experiences, that the equivalent functionality would require two to three times as much C++ or Java.

4.4 Object-Oriented Data Structures and Strategies

We used Perl “packages” (the equivalent of classes in C++ and Java) to hold all ILab data, both persistent and transient. Figure 2 depicts the data structures hierarchy. An Experiment package holds all persistent data: this data is serial-
ized (written *en masse*, retaining data structure hierarchies) to and from disk with the use of Perl's `Data::Dumper` module. In order to reduce the size of the `Experiment` package, several other arrays of packages apportion data that has to be held in lists or arrays: a `ParamFile` package for each input file to be parameterized, a `ParamData` package for each variable that is being parameterized in each input file, and a `Job` package to hold run-specific data. `ParamFile` and `ParamData` hold file- and variable-specific data while the Experiment is being created and edited. In order to run a user's parameter study Experiment, a list of `Job` packages is created: some `ParamFile` and `ParamData` data is transferred to `Job` packages, and additional data is added. The organization of data in `ParamFile` and `ParamData` is "orthogonal" to the way the same data is organized in the array of `Job` packages: this simplifies script creation, submission, and monitoring. Essentially, data is in arrays of arrays during editing/creation, while during submission/monitoring the same data is flattened out into a one-dimensional array of `Job` packages. Both sets of data are serialized when an `Experiment` package is serialized.

Each window or dialog box is also a package, which holds transient data: user interface references and data as necessary, and also "mirror" portions of the current `Experiment` data. This duplication of data makes it easier and more robust to edit previously entered data, since a user can make changes and then cancel the changes without having to restore the original data. Another important advantage is gained from the "mirror" and "orthogonal" approaches: the trade-off is more data, less code. Problems in the data are easier to fix than problems in the code, since they are easier to find, so debugging is easier and faster. Debugging is also facilitated by the following strategies: (1) each package has a "dump" function to print out all variables and (2) each package error-traps the setting of any variable inside the `set` portion of a `get/set` function. A caveat is appropriate here: data duplication is by no means a good or dependable strategy, unless it is closely integrated with code design. This integration means constantly
reviewing the data members of packages, and moving data members as appropriate in order to avoid inconsistencies and incoherencies in the package design.

As much as possible, we avoided the use of inheritance, since we want to keep the code structure simple and intelligible. Some of ILab’s dialog packages are derived from existing Tk packages, but this derivation is only one-level deep, and is fairly transparent. The only data structure that needed to use inheritance is our JobModel package, since the following conditions are true: (1) we have several “job models” already, and they have enough similarities and differences to justify the existence of a base class and (2) more derived job models will need to be added in the future, as ILab is expanded to accommodate more meta-computing environments. The various job models are described in section 5.

Perl is well-known to be a highly flexible language. We were able to further simplify our packages by naming the package members and the get/set functions by the same names, since the Perl interpreter distinguishes the variable from the function by the calling syntax; the variable is $reference->{name}, and the function is $reference->name. Note that Perl already makes it easy to collapse get and set functions into one function, so that only one function accompanies each data member.

Here is an example of this shotgun approach in our Job package, showing the new (constructor) function, two data members, (JobID and Status) and the Status (get/set) function associated with the Status data member:

```perl
package Job;

sub new {  
    my $class = shift;
    my $self = {};  
    $self->{JobID} = undef;
    $self->{Status} = 'NotStarted';
    bless $self, $class;
    return $self;
}

sub Status {  
    # Only allow one of six strings for this field
    my $self = shift;
    my $temp = '_'[0] if @_;  
    if ( defined($temp) )    # set the variable if an argument is passed in
    {  
        if ( $temp eq 'NotStarted' ||  
            $temp eq 'Queued' ||  
            $temp eq 'Running' ||  
            $temp eq 'Stopped' ||  
            $temp eq 'Failed' ||  
            $temp eq 'Done' )       
            { $self->{Status} = $temp; }
        else  
            { print "attempt to set job status to illegal field = $temp\n"; }
    }
    return $self->{Status};  # always return the variable for get function
}
```

Over the course of a large program, this “same-name” model reduces the number of occurrences where the programmer has to reference another part of the code to make sure that names are correct.

For those of our packages that need to be made into base packages (for derivation of mostly similar but slightly different packages), we extend the object-oriented approach by putting the package variables into a “closure”, thereby making these data members less accessible to programming users of the base class.
5 Job Models

In this section, we will describe the various job models that ILab currently supports in order of increasing complexity. The simplest of these models represents an entirely local capability, i.e., all jobs resulting from the creation of the parameter study are also submitted for computation onto the local machine. These job runs occur without the assistance of any scheduler, but may include a parallel job launcher such as “mpirun”. ILab generates a single shell script for each run in the parameter study. Each shell script constructs a main directory for the parameter study (if one doesn’t already exist), and then builds its own subdirectory, uniquely named with an automatically generated parameterization identifier. Files required for input by the user’s executable are copied into the respective subdirectories. The executable is then started. Because no scheduler is assumed, jobs are run sequentially to avoid oversubscribing the local system. This is accomplished by chaining the shell scripts, i.e., the first shell script does its work and then submits the next script in the chain, etc. Note that this submission-by-chaining proceeds even if there is a failure of other commands (e.g., the user’s primary compute executable) within the scripts.

The second job model launches jobs onto a cluster of machines (which may include the originating machine), on each of which the user has an account and an appropriate “.rhosts” file. Each job is implemented with a pair of shell scripts, the first of which remote-copies (via Unix “rcp” command) the second script to the remote location and then executes (via Unix “rsh” command) this script on the remote machine. It is the second shell script that does the work of organizing and creating the directory layout on the remote host, and which then starts the chain of computation. This job model is currently in a sub-optimal state of development because it makes no use of schedulers. We have not built in any mechanism for limiting the number of concurrently running jobs on any individual resource. This implies that the individual compute resources may become oversubscribed. We are planning to add a non-scheduler-based job “limiter” into this job model.

The third job model is similar to the second, except that the presence of a scheduler is assumed. When the scheduler is PBS, the first shell script submits to the scheduler a script containing PBS directives followed by shell commands.

The fourth job model assumes that the Globus metacomputing middleware is used for remote job submission and file manipulation and that a job scheduler (PBS) is used for queuing and starting jobs. The remote script is similar to that of the third job model.

Note that none of the above shell scripts need to be provided by the user; all necessary shell scripts are automatically generated by ILab during the script generation phase. In each of the above cases, a parallel job loader (currently MPI is supported) may be specified.

Note that currently files are not cached onto the remote systems at the time of job submission. We have assumed that users will be submitting into a production level environment, and that routing through a job scheduler will be required by the computer center administrator. This implies that the third and fourth job models will be the most heavily used. The typical usage scenario is that a suite of jobs is submitted through a scheduler, and, as such, the compute resource will be shared with other users. Thus the total time for the entire parameter study to complete will typically be numbered in days, not hours or minutes. This is based on our experience at NASA research centers and on our knowledge of the types of parameter studies users are contemplating. Furthermore, users will typically be submitting their jobs to run on volatile scratch file systems. This is a common requirement since most modern computer centers do not make available to users enough permanent file-system space to accommodate the input and output files of substantial parameter studies. Caching of files is therefore risky since there is no guarantee that by the time an individual parameter study job is started by the scheduler that cached input files will not already have been purged by a periodic file scrubber. It is unrealistic to expect otherwise. However, we have devised a method for caching files only when jobs finally start. This includes a method for guaranteeing that (1) only one process can be copying an input file to a cache so that there is no clobbering during the procedure (this involves a lock file during the caching process) and (2) that files which were previously cached, but then subsequently deleted by a scrubber will be re-cached on demand by the client job. We will be adding these capabilities to the third and fourth job models.

Finally, a few words on the advantages to utilizing shell scripts. We have taken the position that Unix shell languages are the “lingua-franca” of Unix JCL. Our choice is the Korn shell [10] “ksh”, which is a highly expressive language for constructing sequences of commands, and for error-trapping them. With the Korn shell language, background processes and “co-processes” (background processes that can communicate with the parent process) may be easily created. Processes may also be easily monitored and subsequently killed if necessary. Another advantage of using shell scripts is that they may, if desired, be invoked independently of the GUI. There is no requirement that only the ILab GUI can start user processes. Furthermore, those users who wish to may independently modify the shell scripts for their own purposes. The shell scripts are therefore “recyclable”, if desired. Since the commands in the
scripts are interleaved with output statements, these scripts leave a record of their workings, which is used as a log.

ILab may, in part, be described as a GUI that collects information on the locations of the user’s executable and input files, and then assembles the appropriate shell scripts for running this executable. Thus, an additional advantage of using shell scripts is that it is fairly easy to change existing job models or add new ones. This is accomplished simply by modifying the generating code within ILab. In order to simplify the addition of future job models to ILab, we used the object inheritance capabilities of Perl to create a base JobModel package and several derived JobModel packages (LocalJobModel, GlobusJobModel, etc.). New derived job models, e.g. for the metacomputing environments Condor and Legion, can be easily inserted into the existing framework. Additionally, as a special case of creating and launching a parameter study, it is possible, and easy, to use ILab to launch single jobs runs (i.e., a singleton parameter study) into a local or remote compute environment that may require any of Globus, PBS, and/or MPI. Thus, ILab may be used simply as a Unix JCL script generator for launching single jobs, greatly simplifying the launching process. This is especially true in the case where a job will be run on a remote system and requires the migration of input files and executable.

6 Parameter Study Example - a Case Study

Until recently, parameter studies of aerospace vehicle flow characteristics typically utilized two-dimensional computational fluid dynamics (CFD) solvers. This was partly dictated by limitations in the available compute resources, both in terms of CPU time and memory size. Recently, however, because of the increased availability of multi-processor parallel machines with multi-gigabyte memories, it has become feasible to create parameter studies based on three-dimensional CFD codes. Nevertheless, the nature of the current generation of aerospace vehicle flow solvers still makes the overhead for such large parameter studies high. As an example, we chose the Overflow three-dimensional Navier-Stokes flow solver [11]. This modern CFD code implements the overset grid method (overlapping curvilinear grids exchange interpolated boundary information at each time-step). The MPI parallel version of Overflow groups neighboring grids for solution onto individual processors. We applied the Overflow code to the solution of the flow field of the X38 Crew Return Vehicle (CRV), a NASA space vehicle designed as an astronaut escape pod potentially for the international space station. Figure 3 depicts the X38 CRV and several of the body-fitted curvilinear grids which define its surface. The geometry of the X38 CRV is defined by 13 curvilinear body-fitted grids and 115 off-body grids (which are strictly Cartesian in topology). This grid system contains approximately 2.5 million points and since the Overflow code requires some 40 double-precision words of memory per grid point, this results in a total memory requirement per run of approximately 800 Megabytes per run.

![Figure 3: X38 Crew Return Vehicle with several of its computational body grids](image)

We chose to create a 16 × 12 parameter study for two significant flow variables in a portion of the glide regime of the X38: Mach number (basically, the vehicle velocity) and Alpha (the “angle-of-attack”). This results in a two-dimensional parametric study consisting of 192 runs. Each run for the X38 vehicle requires four processors.
Using the ILab tool involves the following steps. First, the user must supply a name and directory for his “experiment”, which is where the records for this parameter study will be kept. Then, the names of the local and remote machines on which the runs will occur must be supplied. Next, an input file directory is named, and the input file(s) to be parameterized are specified. At this stage, the parameterizable input file will be displayed in the special-purpose parameterizing editor. The user parameterizes this file as described in section 4.1, and the 192 parameterized input files are created. Next, the user identifies the executable name and location and also a directory name in which the run subdirectories will be located on each of the executing machines. Options for specifying MPI, Globus, and PBS, and number of processors (four per run, in this case) are set. At this point, the appropriate shell scripts are generated and then initiated. This entire entry process takes under five minutes. However, if starting from a previous experiment, an MRU file may be selected. ILab permits the user to make appropriate modifications to the MRU file using the same entry widgets that are used to create a new experiment. For cases like that described above, it usually takes under a minute to create and start an entire parameter study.

In our experiments, two machines were selected for running the jobs, each of which supported MPI, Globus, and PBS. The scripts that were generated by ILab conformed to our fourth job model. ILab then submitted all jobs to the PBS queues on the selected machines and over the next 24 hours (approximately), all jobs completed. From the resulting solutions, we computed forces and moments for the X38 CRV, and from these, we constructed a plot of the coefficient of lift over drag (Cl/Cd) for the vehicle. This is displayed in Figure 4. Every point in the lattice represents a complete flow solution.

![Figure 4: Coefficient of lift over drag for the X38 CRV](image)

7 CAD Tool Process Specification

Currently, all information describing the user’s process is collected through a series of previous-and-next-wizards, which guide the user through the process specification procedure. Though this model is acceptable for single stage parameterizations, it quickly becomes inadequate for specifying complex user processes. These complex processes may include several stages of parameterization, pre- and post-processing of data, archiving of data, resubmission and restarting of user programs, feedback loops to accommodate multidisciplinary optimization, etc. Currently, we are building a visual capability for complex process specification which will be an alternative to the wizard mechanism. This will consist of a CAD tool for constructing a data-flow diagram which describes the user’s set of processes. The user will be able to construct this diagram by choosing individual process element icons from a palette and placing them in the diagram by drag’n’drop mouse operations. This palette of icons will represent the basic process building blocks such as input file parameterization, moving, copying, or renaming files, running an executable, etc. At each node of the diagram, a right mouse button click will pop-up an appropriate dialog that will query the user for the details required for that particular operation. Internally, a directed graph representing the entire set of processes in the user’s
Experiment is created, e.g., a parameterization followed by the execution of a simulation program, then followed by the execution of post-processing program(s) and archiving. Subsequently, this directed graph is interpreted, and the required individual shell scripts are constructed from the information stored at each node. The construction process consists of assembling the required shell scripts from macros, which in this case are small groups of ILab-provided shell commands that perform the operation the user has requested.

Figure 5 depicts an example of a multi-stage parameterization process. In the first stage, input to a grid generation program (Gridder) is parameterized, resulting in three input files. After running the grid generator, three grid systems have been created. These grid systems will be part of the input to a flow solver (Solver), as will a flow variables input file. It is this flow input file which is subjected to the second stage of parameterization. In the figure, a four-way parameterization has been applied. Each of these four flow input files must be replicated three times to be paired with the three grid files, and each of the grid files must be replicated four times for pairing with the flow input. The result is essentially a two-dimensional parameter study \((3 \times 4)\), but it has resulted from two independent stages of parameterization. This adds a higher degree of complexity to the user’s process, and consequently, to the mechanisms required for assembling and running these jobs. It is, in part, for this reason that we are constructing a more powerful user interface mechanism for specifying and creating parameterization processes.

**Summary**

The needs of our user community have triggered the development of ILab, a flexible parameter study creation and job submission tool. This modern GUI implements a modular experimental workbench for programming research into local and remote job submission methods, complex user process specification technology, and for experimentation with IPG middleware. Our choice of Perl/Tk as a rapid-prototyping development language strongly facilitates experimentation and anticipated further expansion of the core user GUI capabilities. We have proven our ILab product with significant parameter study computations in a distributed environment. We are currently working closely with users whose parameter study requirements are demanding. We are adding these new capabilities to ILab using an advanced CAD-based user-interface technology.
